# WIND EROSION FORCES IN THE UNITED STATES AND THEIR USE IN PREDICTING SOIL LOSS

By E. L. SKIDMORE, *research soil scientist*, and N. P. WOODRUFF, *research investigations leader, Soil and Water Conservation Research Division, Agricultural Research Service*

Soil blowing of agricultural lands is a serious problem in arid and semiarid regions and on sandy soils of the United States. Soil loss from a given cultivated field depends on cloddiness, surface roughness, and surface moisture of the soil; on amount, kind, and orientation of the vegetation; on wind velocity or force; and on distance across the field along the direction of the wind force (11).<sup>1</sup> Information on soil and residue effects on erosion is available in considerable detail (7, 11). However, published information on wind forces for use in determining amounts of wind erosion and for designing wind erosion control practices is meager and is limited to specific areas of the United States (6, 8).

This handbook furnishes detailed information on wind erosion forces for locations throughout the

United States for use in assessing erodibility of field soils and in designing control practices to combat the ravages of wind erosion.

The data presented include (1) relative magnitude of wind erosion forces or the capacity of the wind to cause erosion on unprotected soils, (2) prevailing wind erosion direction, and (3) preponderance of wind erosion forces in the prevailing wind erosion direction. These factors indicate, respectively, potential need for wind erosion protection, proper orientation of erosion control measures, and relative merits of proper orientation of the control methods. The data are presented by months for 212 locations.

A brief description of analysis is presented. Method of analysis in more detail is available elsewhere (10).

## SOURCE AND DESCRIPTION OF WIND DATA

Determining magnitude and direction of wind erosion forces requires analyses of detailed wind data. Detailed wind data of hourly observations of windspeed and direction are scarce. Of the many stations reporting climatological data, only a few record these hourly observations. Those that do are generally airports or military bases. Percent frequency of windspeed and direction are given in Air Force Summaries of Surface Weather Observations (A-B Summaries); Navy Summaries of Monthly Aerological Records (SMAR); and Environmental Data Service publications, Local Climatological Data—Supplement and Summary of Hourly Observations. These wind-data summaries were obtained from the National Records

Center, Asheville, N.C., and were used in the analysis described here.

Available data are for relatively short periods of time, especially data from military installations that were active only during World War II. The recording period for most of the data used ranged from 5 to 10 years, as detailed in table 1 (Appendix).

No effort was made to correct heights of observations to a standard because they were not known at all locations and an attempted correction might not be accurate. Windspeed-height relationships must be known to make valid corrections. Since these relationships are affected by such factors as temperature gradients, surrounding buildings, and surface conditions, they cannot be predicted accurately for the sundry unknown conditions.

<sup>1</sup> Italic numbers in parentheses refer to Literature Cited, p. 8.

## METHOD OF ANALYSIS

The analysis is based on the principle that the capacity of a wind to cause soil movement is proportional to windspeed cubed times the duration of the wind.

Several investigators (1, 3, 12) found that when windspeed was greater than that required barely to move the soil, the rate of soil movement was directly proportional to friction velocity cubed. Friction velocity  $U_*$  is related to velocity profile as expressed by

$$U_* = \frac{U_z}{5.75 \log z/k} \quad (1)$$

where  $U_z$  is the windspeed at height  $z$  and  $k$  is roughness length. Over a specified type of surface and height,  $z$  and  $k$  are constant (1, 5). Therefore,  $U_*$  is proportional to  $U_z$ , and rate of soil movement is proportional to windspeed cubed after the windspeed attains some minimum or threshold speed required to initiate soil movement.

Threshold speeds were reported by Chepil (2) to range from 13 to 30 miles per hour at 1-foot height, depending on the history of the field. A threshold speed of about 11 miles per hour at 1.2 feet was indicated for the conditions of another investigation (3). Malina (9) reported data of O'Brien and Rindlaub in which the amount of sand transported was proportional to windspeed cubed after windspeed reached a "critical velocity" of 13.4 feet per second (9.1 miles per hour).

Wind data are commonly reported in climatological records by speed groups. One common division is between 12 and 13 miles per hour. That corresponds closely to the reported minimum windspeed required to initiate soil movement. Therefore, windspeeds 12 miles per hour and less are considered nonerosive and were not used in computations reported here.

### Magnitude of Wind Erosion Forces

The magnitude of a wind erosion force vector  $r_j$  is obtained by summing, for all speed groups with windspeeds greater than 12 miles per hour, the product of mean windspeed cubed and a duration factor for a specified direction as expressed by equation 2

$$r_j = \sum_{i=1}^n \bar{U}_i^3 f_i \quad (2)$$

where  $\bar{U}_i^3$  is the mean windspeed within the  $i$ th speed group cubed.  $f_i$  is a duration factor expressed as the percentage of total observations that occur in the  $j$ th direction within the  $i$ th speed group. The sub  $j$ 's indicate direction and take values from 0 to 15, inclusive, representing the 16 principal compass directions. They are numbered counterclockwise starting with east, which is

arbitrarily taken as the initial side of the coordinate system. Hence,  $r_{j=0}$  and  $r_{j=1}$  are wind erosion force vectors pointing east and east-northeast, respectively.

The sum of the magnitudes of the wind erosion force vectors for all directions gives the total magnitude of wind erosion forces for the location and is expressed by equation 3. The value obtained by evaluating equation 3 for some location indicates the relative capacity of the wind to cause soil blowing at the particular location.

$$F_T = \sum_{j=0}^{15} \sum_{i=1}^n \bar{U}_i^3 f_{ij} \quad (3)$$

### Prevailing Wind Erosion Direction

The magnitude of erosion forces parallel to a particular direction can be obtained from the wind erosion force vectors. If  $p$  is an imaginary straight line intersecting at the origin of a polar coordinate system and  $\phi$  is the angle between  $r_j$  and the imaginary line  $p$ , the amount of erosion forces caused by  $r_j$  that occur parallel to  $p$  is  $r_j \cos \phi$ . The total wind erosion forces parallel to  $p$  as a function of the orientation of  $p$  are

$$F_{||} = \sum_{j=0}^{15} r_j |\cos(j \times 22.5 - \theta)| \quad (4)$$

where  $\theta$  is the angle between  $p$  and the initial side. Similarly, the sum of the wind erosion forces perpendicular to  $p$  is

$$F_{\perp} = \sum_{j=0}^{15} r_j |\sin(j \times 22.5 - \theta)| \quad (5)$$

Obtaining an orienting line  $p$  so the ratio of the wind erosion forces parallel to line  $p$  to those perpendicular to line  $p$ , symbolized by  $R$ , is maximum tends to maximize wind erosion forces parallel to  $p$  and to minimize wind forces perpendicular to  $p$ . Hence, when  $R$  is maximum,  $p$  is oriented in the prevailing wind erosion direction  $\theta_R$ .

### Preponderance of Wind Erosion Forces in Prevailing Wind Erosion Direction

The value of  $R$  maximum ( $R_m$ ) indicates the preponderance of wind erosion forces in the prevailing wind erosion direction. The greater the value of  $R_m$ , the greater the prevalence of the prevailing wind erosion direction. A value for  $R_m$  of 1.0 indicates no prevailing wind erosion direction and a wind barrier would be equally effective in any direction, whereas an  $R_m$  of 2.0 indicates a prevailing wind erosion direction with wind erosion forces twice as great parallel as perpendicular to prevailing wind erosion direction.

### Distance Across Field Along Direction of Wind Erosion Force Vectors

Since rate of soil movement begins at zero on the windward sides of isolated strips of land and increases with distance downwind (4, 5), it is necessary to know the distance across the field along the direction of wind erosion force vectors.

The distance depends on the angle of deviation of the wind erosion force vectors from right angles to field strip. That is visualized when one represents a field strip by drawing parallel lines on two sides of a wind erosion rose and extending each arm of the rose to the boundaries. The length of the arm then represents the distance wind would travel in traversing the field strip along the direction of the wind erosion force vector. When a force vector is at right angles to the field strip, the distance traveled is equal to field width. As the angles of deviation increase, the distance across the field increases as the reciprocal of the cosine (secant) of the angle of deviation.

It is convenient to express the angle of deviation of wind erosion force vector from right angles to field strip as a function of prevailing wind erosion

direction, and angle of deviation of prevailing wind erosion direction from right angles to field strip.

$$A_j = j \times 22.5 - \theta_R \pm A \quad (6)$$

where  $A_j$  is angle of deviation of  $j$ th wind erosion force vector from right angles to field strip,  $\theta_R$  is prevailing wind erosion direction with east as zero reference, and  $A$  is angle of deviation of prevailing wind erosion direction from right angles to field strip. When  $\theta_R$  is clockwise and counter-clockwise of right angles to barrier,  $A$  is subtracted and added, respectively, in equation 6.

Therefore, the distance across field of width  $W$  along the direction of wind erosion force vector  $r_j$  is

$$D_j = W \sec(j \times 22.5 - \theta_R \pm A) \quad (7)$$

By multiplying the distance across field along the direction associated with each vector by the portion of the total wind erosion forces represented by each wind erosion vector, a distribution of wind erosion forces traveling various distances to traverse the field is obtained.

## RESULTS AND DISCUSSION

The data were analyzed on a high-speed digital computer by the previously described methods. Magnitude of wind erosion forces, prevailing wind erosion direction, and preponderance of wind erosion forces in the prevailing wind erosion direction are presented in table 1 (Appendix) for 212 locations in the United States.

### Relative Magnitude of Wind Erosion Forces

The magnitude of wind erosion forces was above 1,000 for some months at some locations in the Great Plains (e.g., Wichita, Kans.; Great Falls, Mont.). Some coastal areas never reached 100 (e.g., Tallahassee and Jacksonville, Fla.), whereas other locations were never below 400 (e.g., Wichita and Great Falls).

Generally wind erosion forces are greatest in the spring and least in the summer; however, that is not true for all locations. Wind erosion forces were greatest in the summer for some (e.g., Laredo, Tex.; Riverside, Calif.) and greatest in the winter for others (e.g., Great Falls, Mont.; Windsor Locks, Conn.).

### Orientation of Barriers, Stripcrops, and Other Erosion Control Practices

For maximum protection against wind erosion forces, an erosion control practice should be oriented perpendicular to the prevailing wind erosion direction. The prevailing wind erosion direction is consistently the same throughout the year for some locations but varies considerably for others.

One should orient wind barriers, stripcrops, and other erosion control practices for the time of year when field and climatic conditions are most conducive to blowing, i.e., when wind forces are maximum, when soil is dry and deficient in cover and cloddiness, and when crops are most susceptible to damage.

The protection given by a barrier depends not only on the characteristics of the barrier and its orientation relative to the prevailing wind erosion direction but also on the preponderance of wind erosion forces in the prevailing wind erosion direction  $R_m$ .

As an example, in figure 1 we compare the percent of wind erosion forces traveling various distances to traverse a field in December at Great Falls, Mont. ( $R_m=3.6$ ) and in April at Midland, Tex. ( $R_m=1.1$ ).

In figure 1, *a*, for Midland at  $A=0^\circ$  (field strip at right angles to prevailing wind erosion direction), 80 percent of the wind erosion forces travel distances equal to or greater than  $1.1 W$ , and 32 percent travel twice the field width. However, for Great Falls when  $R_m$  is larger (3.6), only 40 and 11 percent of the wind erosion forces travel distances equal to or greater than  $1.1$  and  $2.0 W$ , respectively. In figure 1, *b*, where the field strip deviates  $40^\circ$  from right angles to prevailing wind erosion direction, the angle of deviation makes very little difference at Midland where  $R_m$  is small. However, the percentages for Great Falls at  $A=40^\circ$  are much larger than for  $A=0^\circ$  and are slightly larger than for Midland.

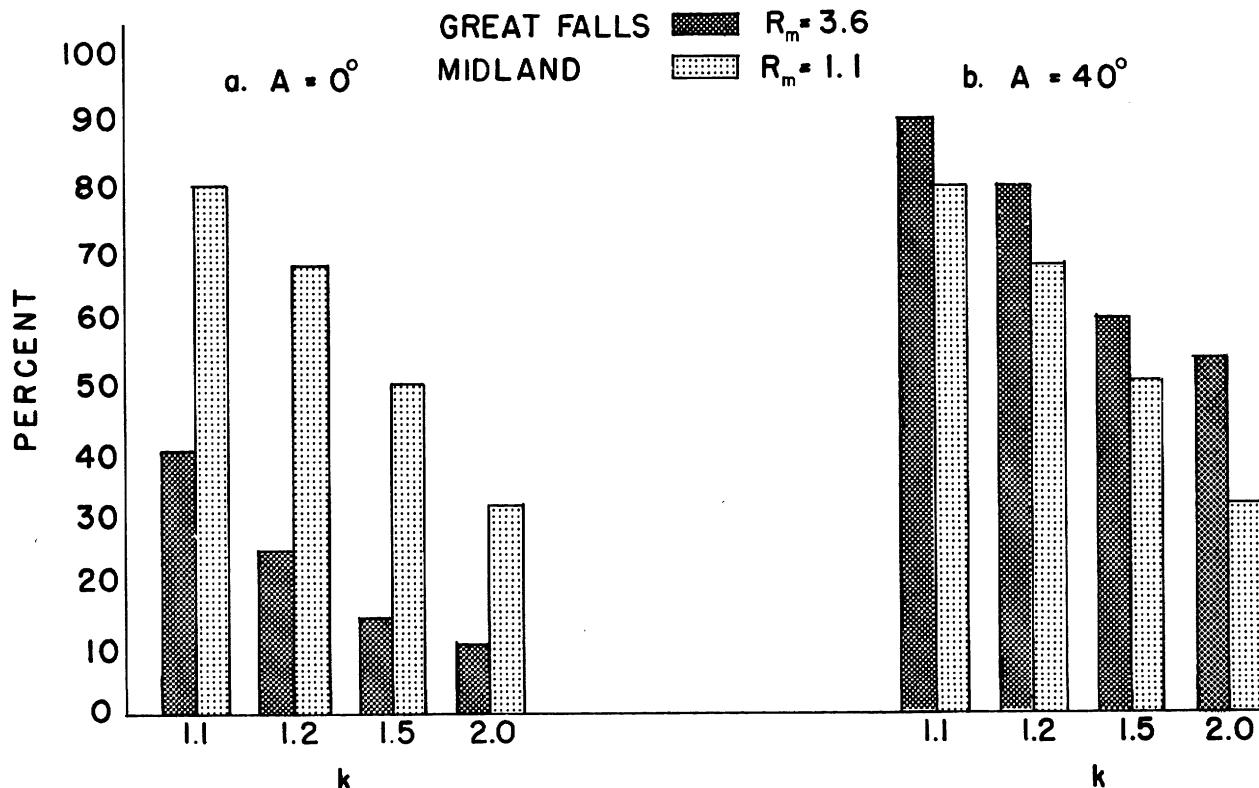

FIGURE 1.—Percent of wind erosion forces traveling distances equal to or greater than some value  $k$  times field width in traversing field strip of width  $W$ , when angle of deviation of prevailing wind erosion direction from right angles to field strip is  $0^\circ$  and  $40^\circ$  for (a) and (b), respectively, at Great Falls, Mont., and Midland, Tex.

As  $R_m$  approaches unity (the smallest value possible for  $R_m$ ), the importance of a particular barrier orientation lessens. Wind erosion forces that occur parallel are equal to those that occur perpendicular to barrier regardless of barrier orientation.

It follows that as  $R_m$  gets larger, more attention should be given to proper orientation of the barrier, as illustrated in figures 2–6. These charts give the percent of wind erosion forces that travel some specified multiple  $k$  of field width in traversing a field strip as a function of  $R_m$  and  $A$ . In general, as  $R_m$  gets larger, the percent of wind erosion forces traveling more than 1.5 times the field width decreases for small angles of deviation of the prevailing wind erosion direction from right angles to field strip. However, for large angles of deviation, the percent of wind erosion forces traveling 1.5 times the field width in traversing field strip increases. That fact should be considered when determining equivalent field width for use in the wind erosion equation and the distance between barriers.

#### Equivalent Field Width

Use of distance  $L'$  across the field along the prevailing wind erosion direction in the wind erosion equation is based on the wind traveling

distance  $L'$  in traversing the field. Unless all wind erosion forces occur along the prevailing wind erosion direction, some of the wind will travel distances greater than  $L'$  in traversing the field. Also, at angles of deviation greater than zero, some wind will travel less than  $L'$  in traversing a field strip. A measure of equivalent field width based on the preponderance of wind erosion forces in the prevailing wind erosion direction as well as deviation of right angle of the strip from prevailing wind erosion direction would be more meaningful.

Suppose that by using the wind erosion equation (11) we have determined that the travel distance  $L'$  of wind in traversing a field strip should not exceed 150 feet to control erosion to a tolerable amount. We now desire to determine the width of a field strip so that no more than 50 percent of the wind erosion forces will travel more than 150 feet in traversing the field strip. Some percentage other than 50 could be selected, but 50 is desirable because half of the wind erosion forces will travel farther and half not so far, so 50 represents the median travel distance; also, it is the percentage best used with figures 2–6.

To illustrate, let us use  $R_m$  of 1.1 and 3.6 in combination with  $A$  values of  $0^\circ$  and  $40^\circ$ . The median distances that wind erosion forces will travel in traversing the field strip are determined by interpolation from figures 2–6.

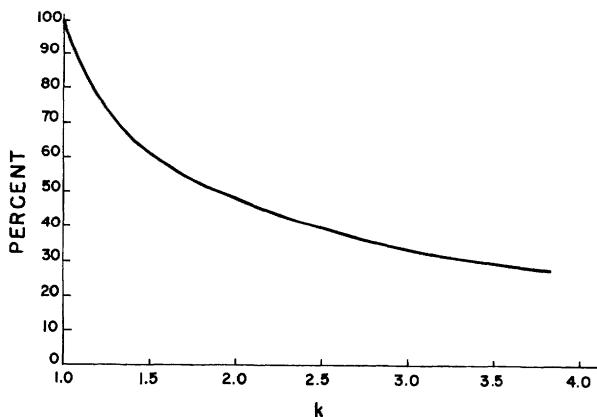

FIGURE 2.—Percent of wind erosion forces traveling distances equal to or greater than  $k$  times field width in traversing field strip for conditions of nonexisting prevailing wind erosion direction ( $R_m=1.0$ ) and all values of  $A$ .  $R_m$  is ratio of wind erosion forces that are parallel to those that are perpendicular to prevailing wind erosion direction. Magnitude of  $R_m$  indicates preponderance of wind erosion forces in prevailing wind erosion direction.  $A$  is angle of deviation of prevailing wind erosion direction from right angles to field strip.

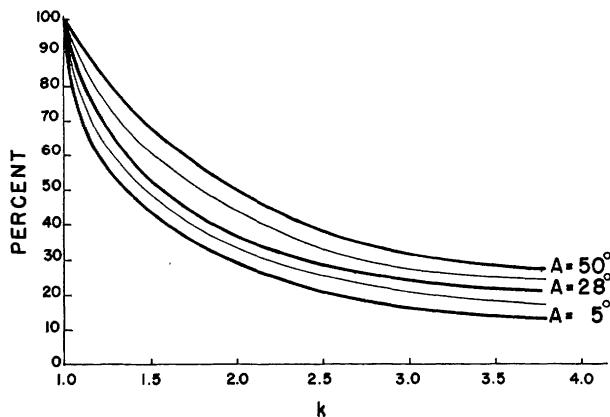

FIGURE 3.—Percent of wind erosion forces traveling distances equal to or greater than  $k$  times field width in traversing field strip for  $R_m=1.5$  and various values of  $A$ .

Remember that  $k$  times field width equals distance traveled by a specified percentage of wind erosion forces in traversing field strip and  $k_{50}W$  equals median travel distance. Therefore, divide 150 by  $k_{50}$  to obtain width of field strip  $W_{50}$  required if no more than 50 percent of the wind erosion forces travel more than 150 feet in traversing the field—the specified conditions of  $R_m$  and  $A$ .

Results are given in table 2 and are compared with width of field  $W_L'$  based on distance across the field along the prevailing wind erosion direction with disregard of the preponderance of wind erosion forces in the prevailing wind erosion direction.

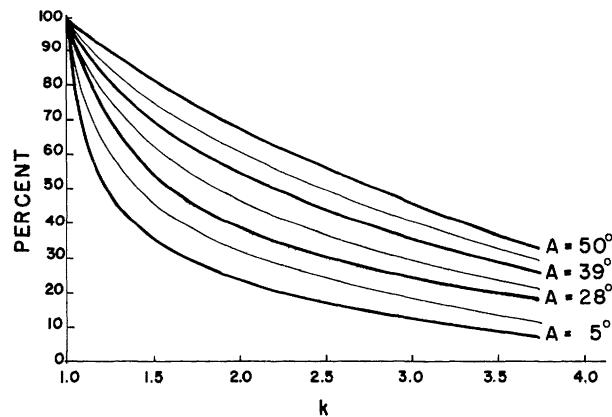

FIGURE 4.—Percent of wind erosion forces traveling distances equal to or greater than  $k$  times field width in traversing field strip for  $R_m=2.1$  and various values of  $A$ .

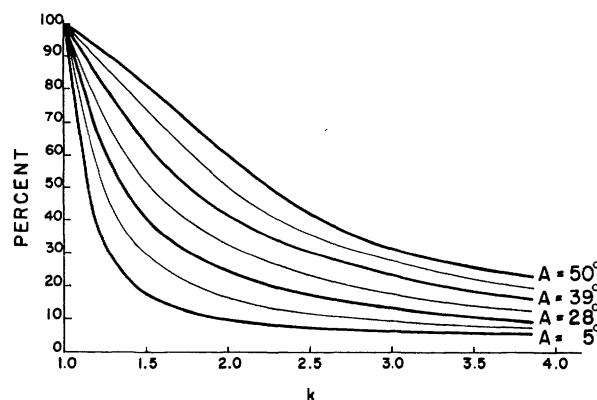

FIGURE 5.—Percent of wind erosion forces traveling distances equal to or greater than  $k$  times field width in traversing field strip for  $R_m=3.0$  and various values of  $A$ .

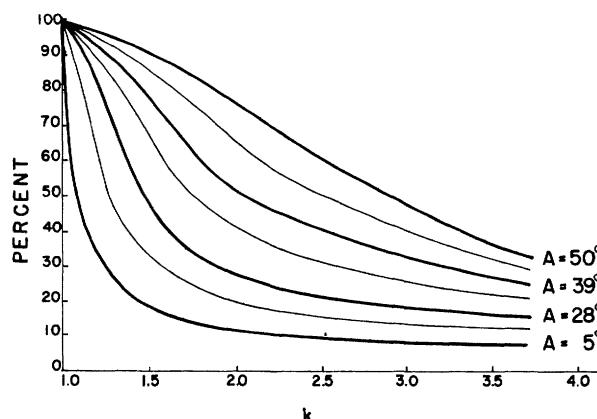

FIGURE 6.—Percent of wind erosion forces traveling  $k$  times field width or greater in traversing field strip for  $R_m=3.8$  and various values of  $A$ .

TABLE 2.—Determination of width of field strip  $W_{50}$  for median travel distance of 150 feet and of width of field strip  $W_{L'}$  so distance across field in prevailing wind erosion direction is 150 feet when preponderance of wind erosion forces ( $R_m$ ) is 1.1 and 3.6 and angle of deviation (A) is  $0^\circ$  and  $40^\circ$

$R_m$	$A$	$k_{50}$	$W_{50}$	$W_{L'}$

## EXAMPLES OF FIELD APPLICATIONS

Data in this handbook can be used in several ways to design wind erosion control practices. Two examples are illustrative.

### Determination of Potential Wind Erodibility of Farm Fields

The amount of erosion  $E$ , expressed in tons per acre per annum, that could occur from a given agricultural field can be expressed as  $E = f(I', K', C', L', V)$ , where  $I'$  is a soil erodibility index,  $K'$  is a soil ridge roughness factor,  $C'$  is a climatic factor,  $L'$  is field length along the prevailing wind erosion direction, and  $V$  is equivalent quantity of vegetative cover (11).

Assume we wish to use the equation and the information given in this handbook to determine the potential erosion  $E$  that might occur in March and October from a field with a 1,320-foot north-south width in the vicinity of Midland, Tex. Since the field is flat and smooth, soil ridge rough-

ness  $K_r = 0$  and soil ridge roughness factor  $K' = 1.0$  (fig. 7). Because it has 800 pounds per acre of flat wheat stubble,  $V$ , the equivalent vegetative cover, is 2,500 (fig. 8). (For other vegetative covers, refer to figs. 9 and 10.) Since dry sieving indicates that 25 percent of the soil fractions are greater than 0.84 mm. in diameter,  $I' = 86$  (table 3).  $C'$ , the climatic factor, appears in figures 11–22 for January through December. The factor is 102 percent for March and 64 percent for October. In this example we shall use median travel distance  $D_{50}$  for  $L'$ .  $D_{50}$  may be determined from this handbook in the following manner:

(1) Refer to data in table 1 (Appendix) for Midland, Tex. Find direction equal to  $45^\circ$  in March and  $90^\circ$  in October, thus indicating the prevailing wind erosion direction has an angle of

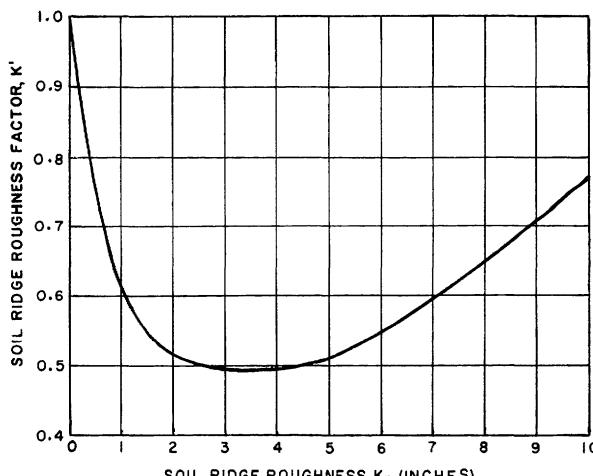

FIGURE 7.—Chart to determine soil ridge roughness factor  $K'$  from soil ridge roughness  $K_r$ .

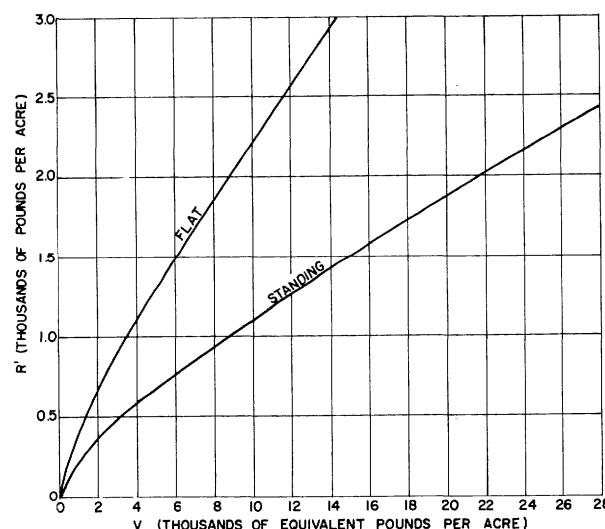

FIGURE 8.—Chart to determine  $V$  from  $R'$  or  $R'_s$  from  $V$  of standing and flat anchored small grain stubble with any row width up to 10 inches, including stover.

TABLE 3.—*Soil erodibility I for soils with different percentages of nonerodible fractions as determined by standard dry sieving<sup>1</sup>*

<sup>1</sup> For fully crusted soil surface, regardless of soil texture, erodibility *I* is, on the average, about one-sixth of that shown.

deviation *A* with reference to the north-south field width of 45° in March and 0° in October. Also note from these data that preponderance or *R<sub>m</sub>* equals 1.2 in March and 1.9 in October.

(2) To find *D<sub>50</sub>* for March, use figures 2 and 3 to determine *k<sub>50</sub>*. For *A*=45°, find *k<sub>50</sub>*=1.90 when *R<sub>m</sub>*=1.0 and 1.85 when *R<sub>m</sub>*=1.5. Since actual *R<sub>m</sub>*=1.2, then by interpolation *k<sub>50</sub>*=1.88 and *D<sub>50</sub>*=*k<sub>50</sub>* field width=1.88×1,320=2,480.

(3) To find *D<sub>50</sub>* for October, use figures 3 and 4 to determine *k<sub>50</sub>*. For *A*=0°, find *k<sub>50</sub>*=1.30 when *R<sub>m</sub>*=1.5 and 1.18 when *R<sub>m</sub>*=2.1. Since actual *R<sub>m</sub>*=1.9, then by interpolation *k<sub>50</sub>*=1.22 and *D<sub>50</sub>*=1.22×1,320=1,610.

Values of *I'*=86, *K'*=1.0, *C'*=102 in March and 64 in October, *D<sub>50</sub>*=2,480 in March and 1,610 in October, and *V*=2,500 may now be used in the wind erosion equation  $E=f(I', K', C', L', V)$  to determine potential soil losses of 40 tons per acre in March and 21 tons per acre in October. The procedure for making these calculations is as follows:

(1) Determine  $E_2=I'K'$ .  $E_2=86 \times 1.0 = 86$  tons per acre.

(2) Determine  $E_3=I'K'C'$ .  $E_3=86 \times 1.0 \times 1.02 = 88$  tons per acre in March.  $E_3=86 \times 1.0 \times 0.64 = 55$  tons per acre in October.

(3) Determine  $E_4=I'K'C'f(L')$

(a)  $L'=D_{50}=2,480$  feet in March and 1,610 feet in October.

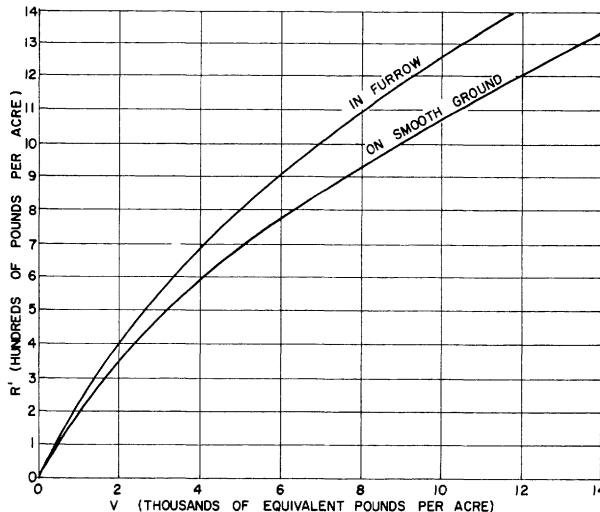

FIGURE 9.—Chart to determine *V* from *R'* or *R'* from *V* of live or dead small grain crops in seedling and stooling stage, above surface of ground, for crop in 3-inch-deep furrow as created by deep-furrow drill on smooth ground.

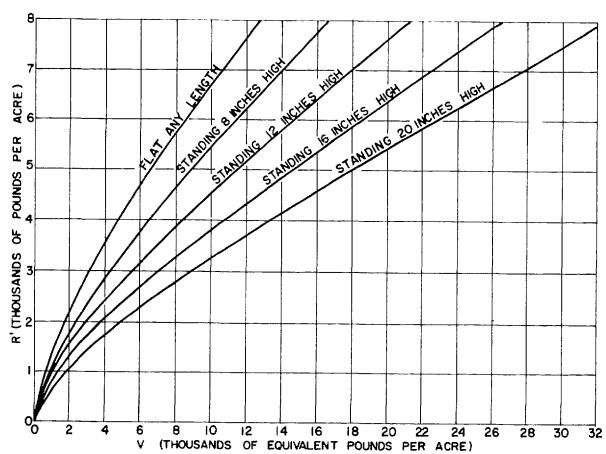

FIGURE 10.—Chart to determine *V* from *R'* or *R'* from *V* of standing and flat grain sorghum stubble of average stalk thickness, leafiness, and quantity of tops on ground.

(b) Use figure 23 to obtain  $E_4$ . Cut out movable  $E_3=I'K'C'$  scale. For March, place it along  $E_2=I'K'$  ordinate so that 88 on movable scale coincides with 86 on ordinate. From movable scale move to right down along 86 interpolated between curved lines 80 and 90 to intersection of  $L'=2,480$  feet, then move horizontally left to movable  $E_3$  scale and read  $E_4=I'K'C'f(L')=82$  tons per acre. For October, place movable scale  $E_2$  ordinate so that 55 on movable scale coincides with 86 on ordinate. Again from movable scale move to right down along 86 interpolated between curved lines 80 and 90 to intersection of  $L'=1,610$  feet, then move horizontally left to movable  $E_3$  scale and read  $E_4=50$  tons per acre.

(4) Determine  $E_5=E=I'K'C'f(L')f(V)$

(a)  $V$  as determined from figure 8 for 800 pounds per acre of residue  $R'$  is 2,500 equivalent pounds per acre.

(b) Use figure 24 to determine  $E_5=E$ . For March, start with  $E_4=82$  on abscissa of figure 24. Move vertically upward to intersection of  $V=2,500$ , then move horizontally left to ordinate  $E$ .  $E=40$  tons per acre. For October, start with  $E_4=50$  on abscissa of figure 24, move vertically to intersection of  $V=2,500$  and horizontally to ordinate and read  $E=21$  tons per acre.

Because these soil loss values are rather high, a farm operator might next logically ask "How much additional residue above the 800 pounds per acre would this field need to prevent soil losses from exceeding a tolerable 5 tons per acre?" That question can be answered by substituting 5 tons per acre for  $E$  in the equation and solving for  $V$ . If that is done using the field conditions for  $I'$ ,  $K'$ ,  $C'$ , and  $L'$  indicated above, one finds that 1,800 pounds per acre of flattened wheat stubble would be required in March and 1,320 pounds per acre

in October. Thus, 1,000 pounds per acre more residue than the existing 800 pounds would be required for adequate protection in March, but only an additional 520 pounds per acre would be needed in October.

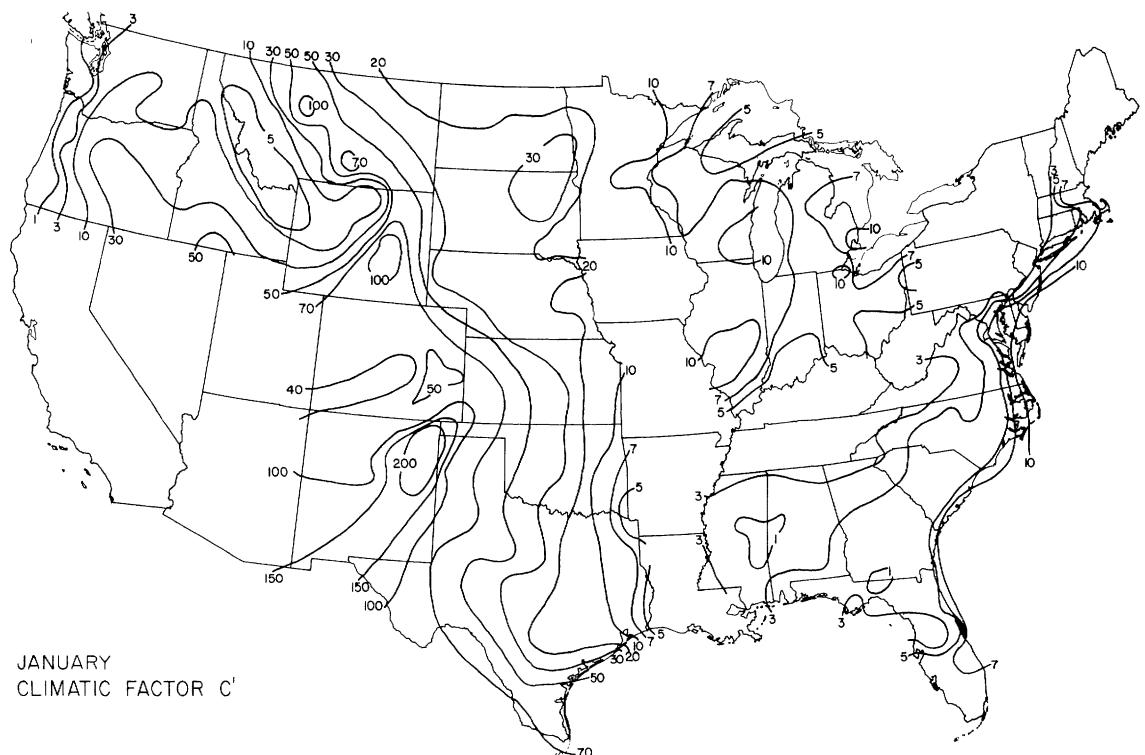

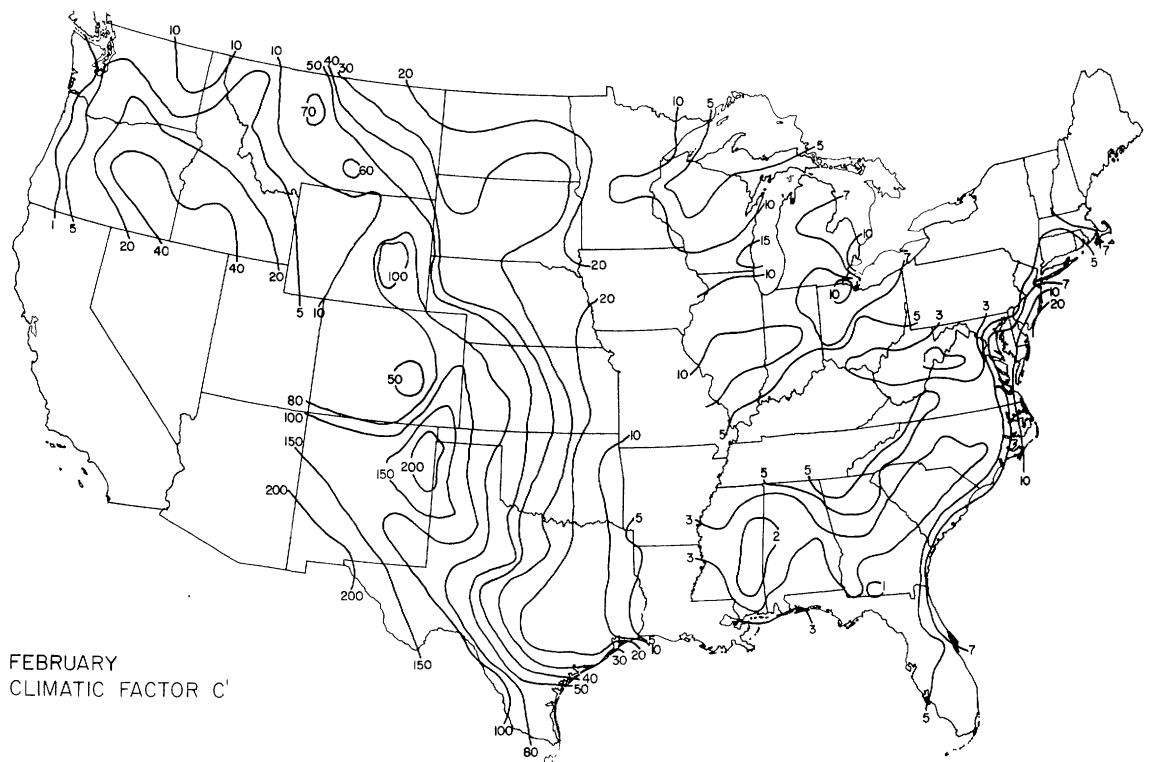

### Determination of Barrier Spacing

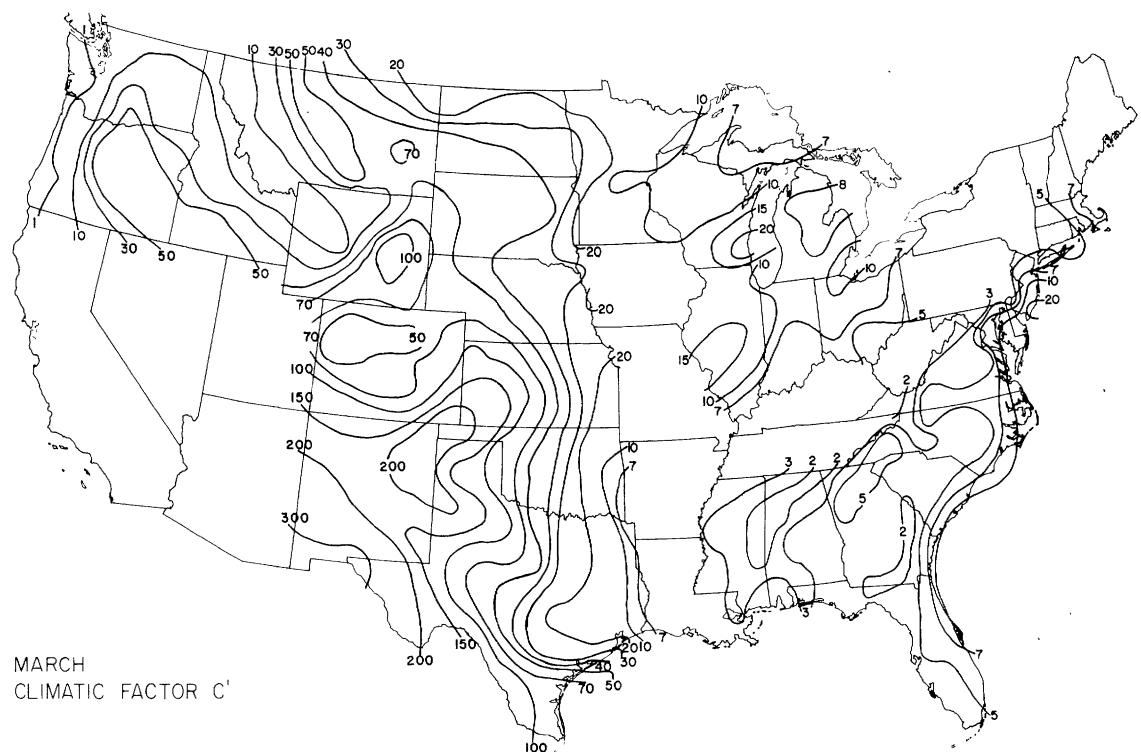

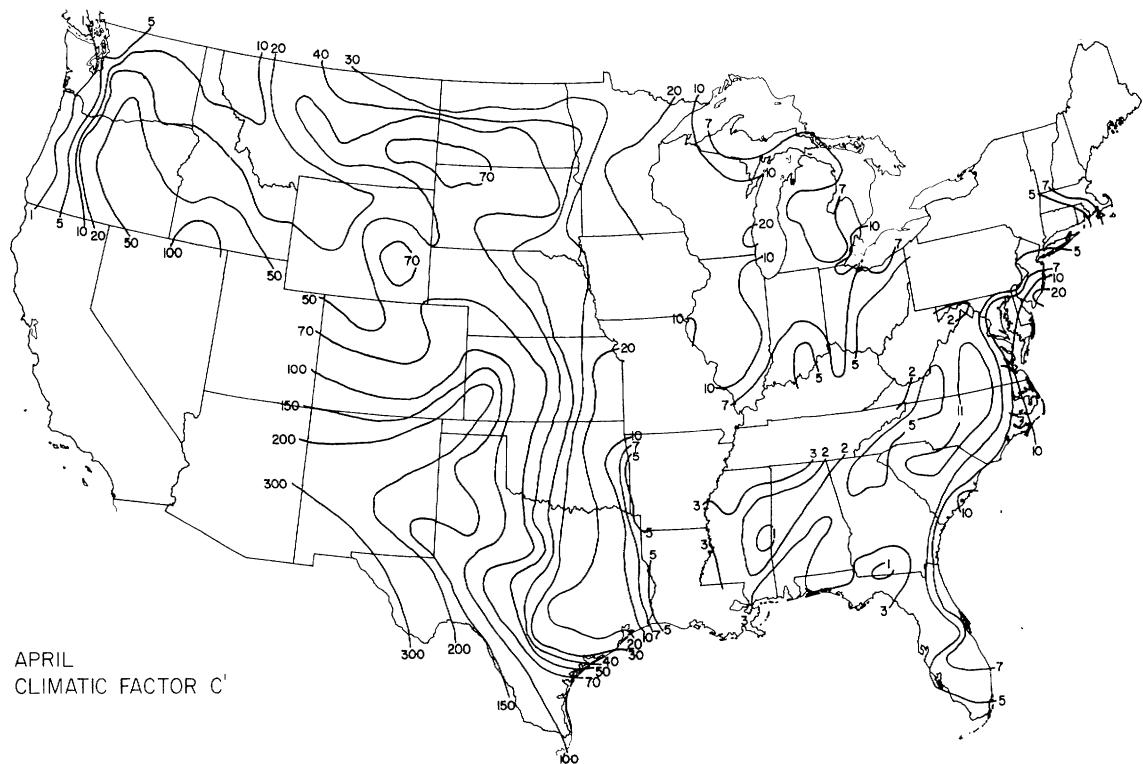

For an example of determining barrier spacing, assume we desire to establish windbreaks to reduce wind erosion of wheat and fallow fields near Goodland, Kans. Information from table 1 indicates that wind erosion forces are greatest in March and April when fields are susceptible to wind erosion. It is decided to design for conditions when wind erosion forces are greatest. Other pertinent information from table 1 indicates that the prevailing wind erosion direction is  $112^\circ$ , north-northwest, and preponderance or  $R_m$  is 2.5 and 2.1 for March and April, respectively. Since the field lies along grid lines and prevailing wind erosion direction is only  $22^\circ$  from north-south, it is decided to orient the barrier east-west.

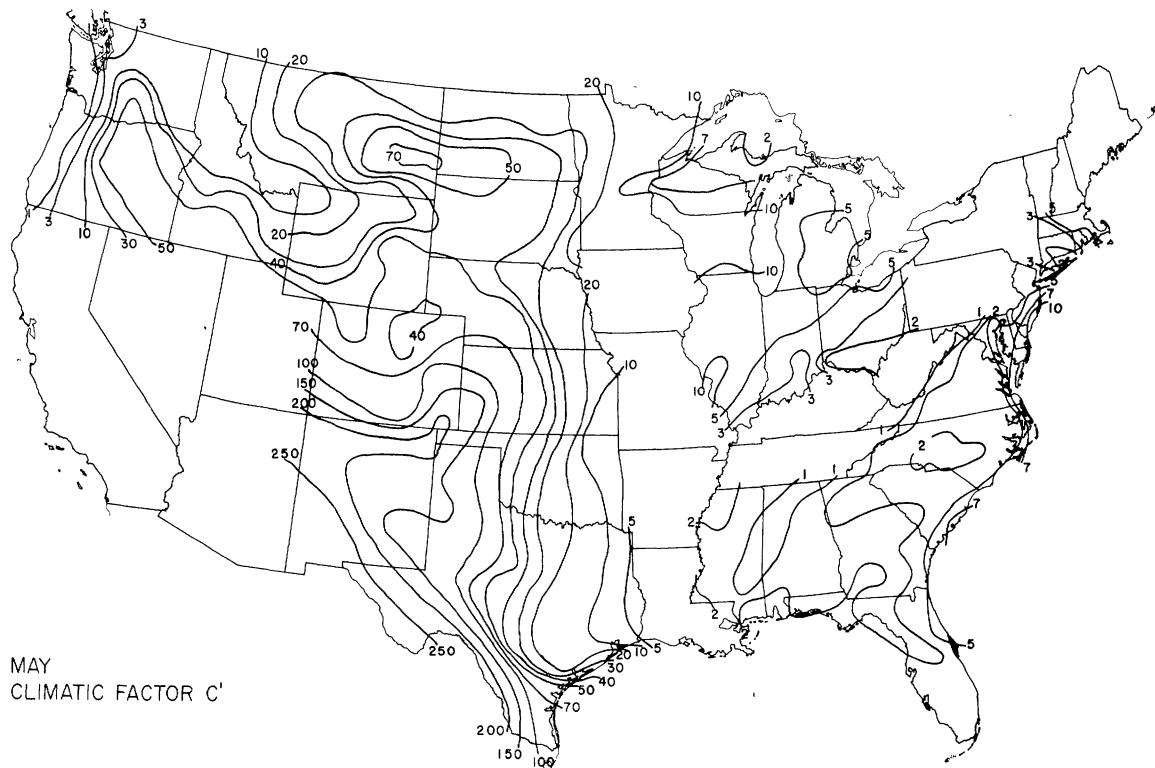

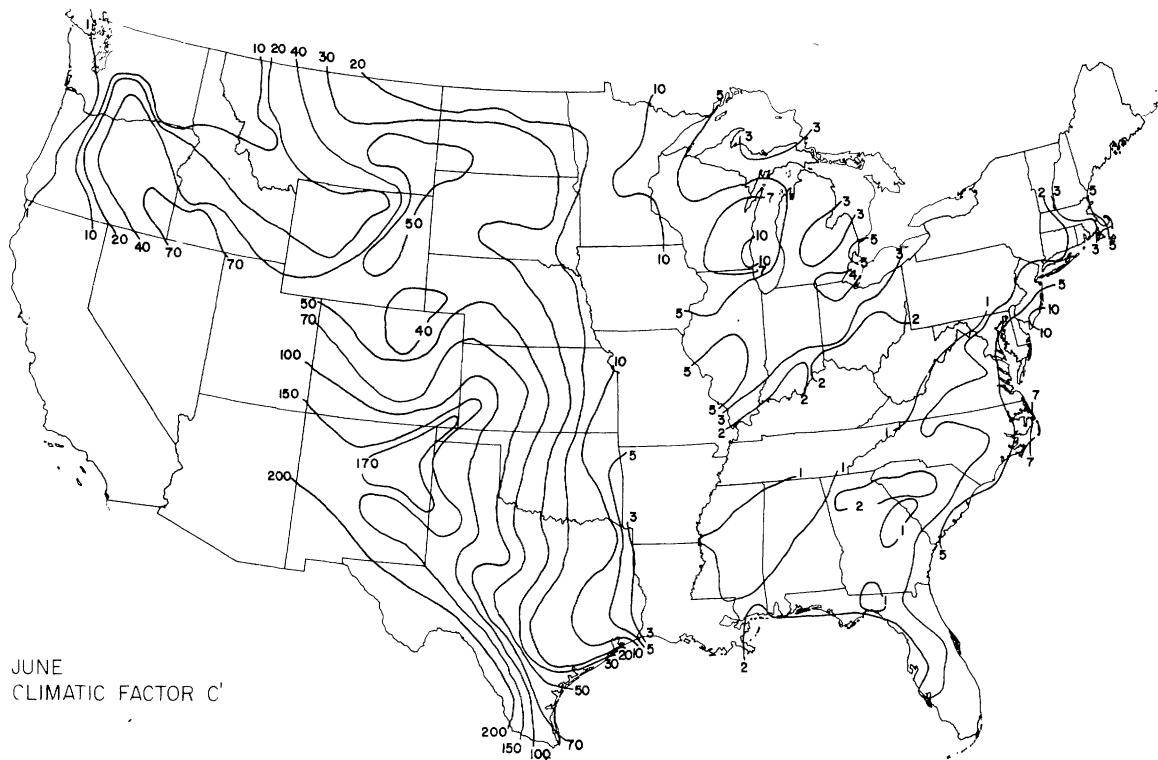

It is decided to base the distance between barrier strips on the distance traveled by 50 percent of the wind in traversing the field strip, or the median travel distance. Based on properties of the barrier to be established and degree of protection desired, it is decided that the median travel distance should not exceed  $30H$ .  $H$  is barrier height. By using figure 4 and interpolating, it is found for  $R_m=2.1$  and  $A=22^\circ$  that median travel distance is 1.5 ( $k_{50}$ ) times the field width  $W$ . If we equate that distance (1.5  $W$ ) to  $30H$  and solve for  $W$ , we obtain  $20H$ . Therefore, based on the design criteria and average wind conditions of the area, wind barriers should be spaced 20 times their height.
